

Chemical and sensory profiles of beers from barley varieties registered in the Czech Republic

ALEXANDR MIKYŠKA – VRATISLAV PSOTA

Summary

Though detailed analysis of malt provides information on its suitability for processing in the brewery, unequivocal relationship between the quality characteristics of the malt and the sensory properties of the beer is not clear. Pilot brewing tests with twelve malting barley varieties registered in the Czech Republic with detailed chemical and sensory analysis were repeated for four years. The results showed some specific characteristics of the varieties and contributed to the knowledge of the relations between the quality features of the malt and the sensory quality of the Czech lager beer and, moreover, the interaction of individual basic descriptors of beer taste. The colour of beers and the polyphenols are affected by decoction mashing, the prediction of beer values from malt analysis is limited. Based on the overall sensory impression, only the best-rated beers (Laudis 550, Bojos and Francin) from the worst-rated KWS Irina variety were distinguished. The harvest year-dependent proteins in barley significantly influenced the malt and beer quality. The varieties were partially distinguished by a principal component analysis of the basic sensory descriptors, but the important factor was the harvest year.

Keywords

barley varieties; malt; beer; sensory quality

Barley varieties submitted for examination for registration in the Czech Republic as malting ones are tested by the Research Institute of Brewing and Malting (RIBM, Praha, Czech Republic) in terms of malt quality. Description of all registered varieties and their malting values are published annually in the Barley Yearbook [1]. Test results of new varieties are published in cooperation of RIBM and Central Institute for Supervising and Testing in Agriculture of the Czech Republic (CISTA, Brno, Czech Republic) [2]. Although detailed malt analysis provides information on characteristics regarding their applicability in beer brewing and on the possibility of reaching a certain level of quality parameters of beer, there is no clear relationship between the quality features of malt and the final quality of beer, in particular its sensory properties. This is generally accepted and, recently, nano-scale brewing tests provided clear evidence that barley genotype as well as its cultivation site significantly contribute to many

sensory descriptors. However, the authors of this study state that larger volumes of beer are needed to evaluate these traits [3].

When comparing the established varieties and evaluating the promising varieties, it is therefore appropriate to add brewing trials to the malting tests. The commercial success of the malting barley variety depends on its acceptance by the breweries in replacing the current varieties with a new variety while maintaining the quality standards of the brewery or for improving the sensory characteristics of the beer. Brewing trials of new varieties on a pilot scale make it possible to detect merits or shortcomings in brewing properties of the varieties in advance of operational deployment and to compare the new raw material with established varieties. This step in the chain breeders – malthouses – breweries that provides timely information on brewing properties of new varieties can save time and resources.

In 2014 (harvest 2013), RIBM launched pi-

lot brewing trials with varieties registered in the Czech Republic. This article summarizes the results of pilot malting and brewing trials of twelve barley varieties that were tested during at least three years, to take into account the effect of the harvest year.

MATERIALS AND METHODS

Malt

Grains of spring malting barley varieties Blaník, Bojos, Francin, Kangoo, KWS Irina, Laudis 550, Malz, Petrus, Sebastian, Sunshine, Vendela and Xanadu were obtained annually (harvests 2013 to 2016) from experimental stations of CISTA. Malts were prepared in a laboratory malting device (KWM Uničov, Czech Republic) according to the methodology of Mitteleuropäische Brautechnische Analysenkommission (MEBAK) [4] (1.5.3 Micromalting) in the following conditions: 72 h steeping at 14 °C with CO₂ exhaustion, steeping periods on 1st day 5 h, on 2nd day 4 h and on 3rd day 3 h. Germination time was 72 h at 14 °C. Pre-drying 12 h at 55 °C, kilning 4 h at 80 °C.

Brewing trials

Fifty liter batches of brews of 11% pale lager beer were brewed in an experimental brewery (Pacovské strojířny, Pacov, Czech Republic). A single decoction mashing procedure was used. The brews were lautered to the constant malt extract in the wort. The lautering rate was measured as the average wort flow rate over the entire operation, lautering and sparging.

Hopping (hop CO₂ extract and Saaz hop pellets 1 : 1) was in three doses, 30 % at the beginning, 50 % after 30 min, and 20 % of hops 10 min before the end of the 80 min wort boiling. The hot break was separated in a whirlpool.

Fermentation was in cylindrical conical tanks (CCT) using lager yeasts, strain RIBM95. Fermentation started at 10 °C, the maximum temperature was 12 °C ± 0.1 °C. The beer was chilled to 5–6 °C and transferred to “lager” CCT. The maturation took three weeks at 1–2 °C. The beer was filtered through a plate filter, bottled and pasteurized.

Malt and beer analysis

The malts were analysed according to the European Brewery Convention (EBC) Analysis Committee methodology [5], using the following methods: 4.3.1 Total nitrogen of malt: Kjeldahl method; 4.5.1 Extract of malt: Congress mash; 4.7.2 Colour of malt: Visual method; 4.9.1 Soluble nitrogen of malt: Kjeldahl method; 4.10 Free

amino nitrogen of malt by spectrophotometry; 4.11.1 Fermentability, final attenuation of laboratory wort from malt; 4.12 Diastatic power of malt; 4.15 Friability, glassy corns and unmodified grains of malt by friabilimeter; 4.16.2 High molecular weight β -glucan content of malt: Fluorometric method; 8.12.9 Total polyphenols in beer by spectrophotometry.

Further, methodology of MEBAK [4] was used, with the methods 3.1.4.2.7 Malt: pH and 3.1.4.11 Mashing method according to Hartong-Kretschmer RE 45 °C (relative extract at 45 °C). Arabinoxylans were determined by DOUGLAS method [6].

Wort and beer analyses were carried out according to EBC methodology [5], using the following methods: 8.3 Wort extract; 9.35 pH; 9.6 Colour; 9.7 Final attenuation; 9.2.1 Original extract of beer; 8.12.9 Total polyphenols; 9.10 Free amino nitrogen; 9.8 Bitterness.

Foam stability was determined by the MEBAK 2.18.2 method [7], using NIBEM Foam Stability Tester (Haffmans, Venlo, the Netherlands) that measures the time during which the foam drops by 30 mm (expressed as seconds per millimetre).

Sensory analysis was carried out using the EBC method 13.10 Sensory analysis (description analysis) [5] by a RIBM panel of trained assessors. Basic descriptors, namely, carbonation, palate fullness, bitterness, astringency, sourness and sweetness (ascending scale 0–5; imperceptible – very strong) were taken into the account. Overall impression, the general assessment of the sample, considering the appropriateness of the all attributes present, including off-flavours, their intensities and the unidentifiable background flavour, were assessed in a descending scale 1–9 (excellent – inappropriate).

The variability of experimental data was represented by standard deviation. The data were processed by two-factor analysis of variance (ANOVA) and by the principal component analysis (PCA).

RESULTS AND DISCUSSION

Malts

Results of the malt analyses showed both differences between the varieties in the particular parameters and the influence of the harvest year (Tab. 1).

The malt extract ranged from 81.9 % (Vendela) to 85.3 % (Malz). The fermentability of laboratory worts, ranged from Bojos and Francin (79.3 %) to Vendela (83.3 %). The 2015 harvest exhibited a trend towards a higher attenuation degree

Diastatic power is expressed in Windisch-Kolbach units as the amount of maltose released from starch by malt enzymes under the conditions of the method [5]. Colour is expressed in EBC units according to Analytica-EBC methodology as the wort absorbance value at a wavelength of 430 nm multiplied by 25 [5]. R – average, SD – standard deviation.

(82.3 %) compared to the other three harvests (81.0–81.4 %).

The average diastatic power of all malts was 362 Windisch-Kolbach units (WK; the amount of maltose released from starch by malt enzymes under the conditions of the method) and showed a considerable varietal dependence. All malts were above the minimum required for Czech lagers (220 WK).

The level of nitrogen compounds in malts harvested in 2013 (10.6 %) and 2014 (10.2 %) was higher than in 2015 (9.5 %) and 2016 (9.9 %), while the soluble nitrogen and proteolytic modification increased, the Kolbach index in first two years (41.4 % and 42.6 %) was lower than in 2015 and 2016 (46.1 % and 47.8 %). The level of nitrogen compounds significantly affects most other technological properties of malt [8], which was reflected in this experiment.

The free amino nitrogen (FAN) concentration of the wort ranged between 141 mg·l⁻¹ and 179 mg·l⁻¹. Low FAN concentrations (below 160 mg·l⁻¹) were determined in Bojos, Malz, Petrus, KWS Irina and Sebastian.

Degradation of starch endosperm cell walls given by friability (average 89.0 %) was higher in 2015 and 2016 harvests and it was variety-dependent. The prescribed minimum for malts for Czech lagers is 75 %. Similar to friability, the concentration of β -glucan in the laboratory wort (average 183 mg·l⁻¹) was variety-dependent. The β -glucan concentration in the wort was dependent on friability ($r = -0.741$).

The pH values of the laboratory worts were in a narrow range of 5.93 to 6.01. The colour was in the 2013 and 2015 harvests (2.6 and 2.9 EBC units; wort absorbance value at a wavelength of 430 nm multiplied by 25) lower than in the 2014 and 2016 harvests (3.2 and 3.1 EBC), Bojos and Malz tended to lower values.

The total polyphenols concentration in worts ranged from 55.2 mg·l⁻¹ (Xanadu) to 77.4 mg·l⁻¹ (Petrus).

Brewing trials

The results of brewing trials are discussed in the context of basic quality criteria with regard to the production of Czech (Pilsner) pale lager beers. The values should be: colour of 8–16 EBC, the difference between apparent and limit attenuation from 1.0 % to 9.0 %, bitterness from 20 to 45 bitter units (BU; represents a concentration of *iso*-alpha bitter acids in beer [5]), pH 4.1–4.8 and total polyphenols concentration from 130 mg·l⁻¹ to 230 mg·l⁻¹.

Wort lautering

The speed of first wort lautering and sparging represents a monitored technological parameter of the malt processability in the brewhouse. The average flow rate, throughout the entire operation, of Malz, Blaník, Laudis 550, Petrus and Sunshine brews was below the set average (Fig. 1), significant was the difference between the worst (Blaník, Malz) and the best varieties (KWS Irina). The lautering rate level for 2013 malts was significantly lower than for malts from other three years. The malts from 2013 had the lowest proteolytic modification.

Negative effects on lautering are attributed to non-starch polysaccharides, β -glucans and arabinoxylans, and also to substances of a protein nature [9–11]. The lautering rate correlated with Kolbach index and soluble nitrogen of malt ($r = 0.333$ and $r = 0.498$, respectively). In this study, the lautering rate had no conclusive link to non-starch polysaccharides, although some malts had a β -glucan concentration well above the limit of $200 \text{ mg} \cdot \text{l}^{-1}$ [12]. However, the β -glucan concentration varies during the brewing process according to malt processing technology, so the correlation between malt and beer is small [13]. The low mash-in temperature and decoction mashing reduce the β -glucan concentration in the wort [14, 15].

Our results indicated a lower lautering rate of Blaník (high β -glucan) and Malz, by 20% lower than that of the best-flowing Francin and Sebastian varieties.

Physico-chemical profiles

The results of the analysis of sweet worts, hopped worts and beers are summarized in Tab. 2–4.

Fig. 1. Speed of lautering of experimental worts.

R – average.

Colour

Colour is one of the basic sensory attributes of beer. Its value is a part of the beer's style and of the given beer brand. Colour of malts Bojos, Malz and Sebastian was below the average value for the entire set of malts (2.94 EBC). The colour of the decoction wort corresponded only partially to the malt colour ($r = 0.617$, $n = 46$). Thus, especially for Blaník and, to a lesser extent, for Petrus, Francin and Sebastian, the colour value of the decoction wort was lower than those of malt and lower than the average of the whole set (6.07 EBC; Fig. 2). Colour substances in sweet and hopped wort are formed by thermal action, oxidation of polyphenols, Maillard reaction (reaction of amino acids and reducing sugars) and caramelization [15]. The reaction rate increases with temperature. Due to mash boiling and longer mashing time, decoction worts have a higher colour value com-

Fig. 2. Comparison of colour of malt, sweet wort, hopped wort and beer.

pared to infusion worts. The colour value of the decoction wort correlated with FAN in the wort ($r = 0.454$, $n = 46$) and with the soluble nitrogen in malt ($r = 0.390$) at a $P = 0.01$.

During wort boiling, the colour value increases due to both the heat load and the reactions of hop substances [15]. The average colour value of hopped wort was 9.31 EBC. The differences in the sweet worts were maintained in the hopped wort, the colour values of the sweet and hopped worts strongly correlated ($r = 0.811$). During fermentation and maturation of beer, the colour value decreased, changes were proportional to the wort colour (wort/beer: $r = 0.836$) and the average beer colour (6.24 EBC) was close to the decoction sweet wort colour. The colour values of sweet worts correlated with the colour values of beers ($r = 0.726$). The relationship between malt and beer ($r = 0.445$) was significantly weaker. The colour prediction of the beer produced by decoction mashing based on malt colour is thus inaccurate. The colour values of beers ranged from 4.8 EBC to 9.6 EBC, the lowest were Blaník (4.8 EBC) and Sebastian (5.4 EBC), markedly higher was Kangoo (9.6 EBC; Fig. 2, Tab. 5). It is obvious that for barley varieties lower in malt modification, lower beer colour values can be expected.

The colour of beer depends, in addition to malt, on the technical and technological conditions of its processing in the brewing process. Lower heat load and lower oxygen exposure at mashing and wort boiling reduce the resulting beer colour.

pH

The pH value of malt and beer is relevant in several respects. The activity of saccharolytic and proteolytic enzymes in mashing is significantly affected by pH of the malt. Usual pH of laboratory wort from Pilsner malt is 5.6–6.0. For starch conversion, the optimum pH value of mash is 5.3. The decrease in pH during fermentation and maturation of beer promotes clarification and natural colloidal beer stability. Protein-polyphenol complexes have an isoelectric point, and thus the lowest solubility, in the acidic pH range. The pH value of the beer itself also participates in organoleptic sensation. The Czech pale lagers have a slightly higher pH than similar foreign beers [16].

The laboratory worts had largely balanced pH values. Decoction worts showed a trend towards lower values for Blaník, Bojos, Francin, Malz, Petrus and Vendela in comparison with other varieties (Fig. 3). The relationship between pH of malts and decoction worts or beers was inconclusive. Values of sweet worts and hopped worts

Fig. 3. Comparison of pH value of malt, sweet wort, hopped wort and beer.

strongly correlated ($r = 0.970$), while the relationship between hopped wort and beer was less pronounced ($r = 0.606$). The colour of the beers slightly but conclusively correlated with pH of the beers ($r = 0.492$; $P = 0.01$). The colour is partly composed of oxidized polyphenolic compounds [15] with a transition between colourless and coloured form being dependent on the ambient pH.

Total polyphenols

High total polyphenols are one of the characteristics of Czech lager. The average concentration of total polyphenols in the malt sample set was $67.8 \text{ mg}\cdot\text{l}^{-1}$ (Fig. 4). Bojos, Blaník, Laudis 550, Francin, Kangoo and Xanadu were below this average. Polyphenols in barley grains and malt are bound in cell structures along with polysaccharides and proteins. They are located in the cell walls of both the endosperm, especially in the aleurone

layer and the malt grain shells, i.e. in the pericarp, testa and lemma, which contain mainly flavonoid substances the carrier of which is the hordein protein [17]. Thus, their concentration in the wort depends on the intensity of mashing and the sparging of spent grains.

Concentration of total polyphenols in malt correlated with proteolytic and cytolytic modification, Kolbach index and friability ($r = 0.377$, $r = 0.356$; $P = 0.05$). For decoction wort, this relation was closer ($r = 0.532$, $r = 0.431$, $P = 0.01$). Total polyphenols in laboratory and decoction sweet worts correlated ($r = 0.519$).

The concentration of total polyphenols increased between sweet wort and hopped wort by about 25 % (from $188 \text{ mg}\cdot\text{l}^{-1}$ to $254 \text{ mg}\cdot\text{l}^{-1}$). During fermentation and maturation, it dropped to the concentration close to that of the sweet wort (beer average $182 \text{ mg}\cdot\text{l}^{-1}$) as a result of the precipitation of the tannin-protein complexes in

Fig. 4. Comparison of total polyphenols concentration for malt, sweet wort, hopped wort and beer.

beer. The relationship between sweet wort and hopped wort ($r = 0.747$) and hopped wort and beer ($r = 0.735$) were strong whereas the relationship between the extremes, malt and beer, was weak ($r = 0.210$). However, polyphenols in malt affect their quantity in beer and there was a significant difference in the total polyphenol concentration in beer between the groups Blank, Bojos and Laudis 550 ($160\text{--}165\text{ mg}\cdot\text{l}^{-1}$), and between the groups Vendela and Sunshine ($195\text{ mg}\cdot\text{l}^{-1}$ and $215\text{ mg}\cdot\text{l}^{-1}$). The generally accepted fact is that two thirds of polyphenols in beer come from malt [18, 19]. However, their content in hop products varies widely ($0\text{--}60\text{ g}\cdot\text{kg}^{-1}$) [20] and, therefore, the level of polyphenols in beer will also depend on the hopping.

Foam stability

Foaming ability and foam stability are among the key attributes of lager beers. It is generally known that proteins and glycoproteins are foaming agents, while bitter hop substances are foam stabilizers. Surface tension and hence foam stability is reduced by lipids, fatty acids, higher alcohols and esters. The stability of the foam is thus a result of factors with favourable and negative effects, i.e. substances contained in beer [21–25].

The foam stability was in the range of $8.00\text{--}11.00\text{ s}\cdot\text{mm}^{-1}$ (Fig. 5). Hence, all beers under study were in the category of well-foaming beers ($7.33\text{--}8.33\text{ s}\cdot\text{mm}^{-1}$) [7]. In varietal averages, all beers, except of Vendela, were excellent foaming beers (above $8.33\text{ s}\cdot\text{mm}^{-1}$). The results for Vendela were significantly lower than those of Francin, Sebastian, Sunshine and Xanadu. Foam stability correlated inversely with proteolytic modification, Kolbach index ($r = -0.570$). In the harvests of 2015 and 2016, a number of barleys tended to high proteolytically modified malts, which was reflected by the foam stability being lower in these years.

Sensory profiles

In this study, the sensory quality of beers was evaluated mainly from the perspective of barley varieties. The varietal averages given below related to the variety's results over the entire four-harvest period under review. The overall sensory impression score in the whole set of 34 beers ranged from 3.6 to 5.8 points of a nine-point scale (1 – best, 9 – worst; Tab. 5) The average quality in individual years was different, the year 2014 differing from the following years (2013 – 4.1; 2014 – 5.2; 2015 – 4.7; 2016 – 4.3 points). Varietal averages ranged from 4.3 (Laudis 550) to 5.3 (KWS Irina). Bojos, Francin, Laudis 550, Malz and Sunshine tended to better results, distinguished being only

Fig. 5. Comparison of foam stability values of beers.

R – average.

top-rated beers (Laudis 550, Bojos and Francin) from the worst-rated KWS Irina.

The overall impression consists of the complex effect and balance of the partial components of the aroma and taste, the basic descriptors are carbonation, palate fullness, bitterness, sweetness and sourness. Moreover, the overall impression includes a critical appraisal of off-flavours. The carbonation of beers was fairly balanced in the varietal averages (Tab. 5). Beer carbonation is caused by dissolved carbon dioxide, perceived by tactile receptors activated by the presence of bubbles in the liquid, and also by pain receptors, reacting to the conversion of carbon dioxide to carbonic acid. It can be influenced by pH and colloidal substances in beer [26]. Surprisingly, carbonation did not correlate with carbon dioxide concentration, while the relationship with pH was significant ($r = -0.455$).

The palate fullness is a marker of Czech pale beers, in particular lagers. Varietal averages did not differ and ranged from 2.1 to 2.5 points on a 0–5 scale (Tab. 5). Francin, Malz and Petrus tended to lower values. The palate fullness correlated with pH ($r = 0.505$) and sensory bitterness of beers ($r = 0.380$), thus a synergic effect of malt and hops was likely. Factors influencing the sensory perception of the palate fullness of beer are not fully elucidated. It is generally believed that a higher wort extract and a lower attenuation, i.e. a higher viscosity and unfermented extract, dextrins, sugars and proteins in beer have a beneficial effect [18]. A significant role is attributed to proteins with a molecular weight greater than 10 kDa [27].

The astringency of beers was low, varietal averages ranging from 1.1 (Bojos, Malz, Kangoo) to 1.7 (KWS Irina; scale 0–5; Tab. 5, Fig. 6). The

Fig. 6. Principal component analysis of basic sensory descriptors of beers (carbonation, palate-fullness, bitterness, sweetness, sourness).

astriogeneity inversely correlated only with the difference between apparent and limit attenuation ($r = -0.417$). Higher concentration of unfermented extract could probably reduce the astringency, which is attributed to certain polyphenol substances from malt [28, 29], hops [19] and the alkaloids hordatins derived from malt [30].

The beers sweetness of varieties ranged from 1.5 (Laudis 550, Petrus) to 2.25 (Sebastian, Sunshine; scale 0–5). The beers of Laudis 550, Malz and Petrus exhibit a lower sweetness compared to Sebastian, Sunshine, KWS Irina and Xanadu (Tab. 5). The sweetness correlated weakly with palate fullness ($r = 0.360$) and the carbon dioxide ($r = -0.487$), carbonation being able to suppress the sweet sensation.

The sourness of beers ranged from 1.6 (Blaník, Laudis 550, Sebastian, Sunshine and Xanadu) to 2.0 points (Vendela; Tab. 5). The perception of sour taste, caused mainly by simple organic acids, depends largely on the overall habitat of beer.

The results of PCA (Fig. 6) show a partial distribution of the varieties but, at the same time, the impact of the harvest year is noticeable, in particular the results of 2013 being different from those of the next three years and this difference formed a considerable part of the variability of the data. The results reflected the fact that only extreme varieties were distinguished in the overall impression.

CONCLUSIONS

The study showed some specific characteristics of barley varieties and contributed to the knowledge on the relations between the qualitative markers of malt and the chemical and sensory profile of lager beer. An important factor is decoction mashing as prediction of beer colour and total polyphenols based on malt analysis is limited. This study shows the significant impact of the harvest year on the quality of the malt prepared by the unified malting process. The analytical profile, saccharolytic, proteolytic and cytolytic modification, and consequent values of soluble nitrogen, limit attenuation, colour and pH, were found to be influenced by the harvest year. This was also reflected by the analytical and sensory profile of beer. In the 2013 to 2016 harvests, there were different weather conditions during vegetation and harvesting [31, 32]. In 2013, despite unfavourable course of the cultivation period, spring barley achieved favourable protein content and favourable average starch content. Harvests 2015 and 2016 were performed under unfavourable weather conditions with frequent showers and storms, which caused barley grains to contain more nitrogenous substances [33]. The overall sensory impression of beers depended on the harvest year. Even so, statistical analysis facilitated partial discrimination of varieties, in particular the top-rated from the worst-rated. In order to reveal the varietal specificity, a long-term evaluation of the varieties in the brewing tests is necessary.
